Abstract: Mineral detection using remote sensing techniques is important since it saves the time and effort of carrying out manual land surveys. In this paper a novel algorithm, which can be used to detect ilmenite using hyperspectral image analysis is discussed. To investigate this task, a hyperspectral image obtained from the Earth Observing-1 (EO-1) satellite's Hyperion sensor was used. In the proposed algorithm, first, principal component analysis (PCA) was used for dimensionality reduction and an Euclidean distancebased method was used to extract the pixels containing soil. Thereafter, lab spectral data of typical ilmenite deposits were considered as the reference and a correlation factor analysis was carried out to determine the soil pixels, which are most likely to contain ilmenite and most unlikely to contain ilmenite. Using these two sets of pixels, a training set was constructed to apply Fisher's discriminant analysis (FDA) in order to separate the dataset into two distinct classes – ilmenite and non-ilmenite. Based on the spectral similarity, each pixel of the image was classified under one of these classes. This paper also introduces a probability-based approach to obtain results that are more accurate. A probability density function was designed considering the spatial distribution of the mineral. Thereafter, classification was done considering the probability measure as well. Lab tests performed on the soil samples collected from the locations, which were detected by the algorithm validate that the algorithm is accurate.

Keywords: Correlation coefficient, data engineering, Fisher's discriminant analysis, principal component analysis, probability-based approach, remote sensing.

INTRODUCTION

A hyperspectral image contains information corresponding to a large number of continuous wavelengths. This facilitates the analysis and detection of intricate details of a given image. As the existence of a particular surface mineral results in a different composition of soil, compared to that of the places where the respective surface mineral is unavailable, imageprocessing techniques can be used to detect possible deposits of surface minerals. The use of satellite images is a non-intrusive and economical way for surface mineral detection as it avoids strenuous land surveys and soil testing. Since hyperspectral data contains richer information in the form of contiguous spectral bands compared to multispectral images, the detection process is more accurate and reliable.

A number of papers have been published in the recent past, proposing different methods of determining possible surface mineral deposits using hyperspectral imagery. Applicability of hyperspectral data to determine trends in hydrothermal alteration intensity in and around the Izok Lake Volcanogenic Massive Sulfide (VMS) deposit in Northern Canada has been discussed by Laakso *et al.* (2016). An efficient procedure for mineral mapping is discussed by Notesco *et al.* (2014), with a unique hyperspectral remote-sensing fingerprint in the

longwave infrared spectral region enabling identification of the most abundant minerals in the continental crust - quartz and feldspars. The presence of copper in Basavanakote, Karnataka was found using hyperspectral remote sensing techniques by Aravinth & Roopa (2017). A new method has been introduced to extract features using mineral absorption by Zhao et al. (2017). Here, Reference Spectral Background Removal (RSBR) has been introduced into mineral absorption feature extraction from high vegetation density areas. Diagnostic absorption feature has the potential to be the key factor in mineral information extraction. Saralıoğlu *et al.* (2016) have attempted to explore minerals with hyperspectral image fusion. Due to the insufficient spatial resolution of current hyperspectral image sensors, a single pixel might include more than one mineral. This paper has revealed a method to overcome this problem by fusing such an image with a high-resolution image. Niranjan *et al.* (2016) have presented a study of minerals and vegetation in explored fields around the San Juan coal mines west of Farmington, New Mexico. Here, Minimum Noise Fraction (MNF) and Pure Pixel Index (PPI) methods are used for the extraction of endmember fraction, and spectral signature matching procedure is done with the United States Geological Survey (USGS) spectral library. Swamy *et al*. (2017) have carried out a dimension reduction based algorithm on complex wavelet filter bank and the mimetite mineral spectral signatures, and classified using the orthogonal subspace projection method. The desired mimetite spectral signature is segregated from the mixed pixels and estimated in the presence of two other minerals with the help of complex wavelet filter bank and spectral matching. Vithana *et al*. (2019) have exploited the relative proximity of spectral signatures among classes of remotely sensed hyperspectral images in order to generate an adaptive hierarchical structure for image classification. This enables a level-by-level optimisation for clustering at each stage of the hierarchy. Ekanayake *et al*. (2019) have proposed a novel method for hyperspectral unmixing, in which the fundamental notions of independent component analysis are utilised to improve the accuracy of the standard non-negative matrix factorisation algorithm. This method proves to be highly accurate with regard to hyperspectral image classification.

This paper presents a method of detecting possible ilmenite deposits in the Northeastern region of Sri Lanka, using concepts related to data engineering, mathematics, machine learning and signal processing, on a hyperspectral image of the respective region obtained by the Earth Observing-1 satellite's Hyperion sensor. The detection algorithm first deals with classifying

the pixels in the region under its sub components. It was observed that the selected geographical region constitutes mainly of vegetation, water bodies, paddy fields, beaches with sand, and soil. Thus, three main classes, i.e. 'vegetation', 'water bodies' and 'sparse vegetation and soil' were defined. Here, the class 'sparse vegetation and soil' covers areas where there are paddy fields, soil and sand. Throughout the rest of this paper, we refer the 'sparse vegetation and soil' class as 'soil'. Thus, the primary intention is to classify the pixels in the selected image region under the relabelled classes, 'vegetation', 'water bodies' and 'soil'. Then, the pixels containing soil are extracted for further analysis in order to find out the regions containing ilmenite. A spectral signature for the composition of soil where ilmenite deposits exist was created using data available in spectral libraries. With the aid of the reference spectral signature created, a correlation analysis was carried out to select a training sample of pixels, which were then used to develop the detection algorithm. The results of the analysis were validated by a field visit, where soil samples were collected from several locations predicted by the algorithm. The lab results confirmed the presence of ilmenite in locations detected by the proposed method.

METHODOLOGY

Dataset

The hyperspectral image that was used in this analysis was captured by the Hyperion sensor (USGS, EO1H1410532005260110PU_SGS_01) attached to the NASA's Earth Observing - 1 (EO - 1) satellite. The Hyperion sensor has the capability of resolving spectral bands from 0.4 µm to 2.5 µm - belonging to visible, near infrared and short wave infrared regions of the electromagnetic spectrum, with a spatial resolution of 30 m and a swath width of 7.5 km. The Hyperion sensor provides for two grating image spectrometers with detailed spectral mapping across all channels with high radiometric accuracy. These two spectrometers, VNIR (Visible and Near-Infrared) and SWIR (Short Wave Infrared) had been used to obtain the hyperspectral images consisting of 242 bands spanning across a range of wavelengths, from 355.59 *–* 2577.08 nm (Griffin, 2005).

As seen in Figure $1(a)$, the hyperspectral image subjected to analysis in this paper is a strip along the Northeastern region of Sri Lanka, which covers a geographical area of approximately 7.5×100 km². Its true colour version is shown in Figure 1(b). The geographical coordinates of the image are as follows:

Figure 1: (a) The geographical location of the hyperspectral image strip; (b) true colour version of the hyperspectral image strip (the area chosen for analysis is marked by a red square); (c) the area chosen for analysis - image size 273×251 pixels

The respective hyperspectral image strip was obtained from the USGS database (USGS, EO1H1410532005260110PU_SGS_01). The Level 1Gst (L1Gst) product was used since all radiometric and systematic geometric corrections are performed in the L1Gst product. In addition, a 90-meter Digital Elevation Model (DEM) has been employed in this particular product. The image was available in the form of 242 monochrome Geo 'TIFF' images belonging to each of the 242 spectral bands. The size of the image was 7481 \times 1851 pixels and each pixel covered an area of 30 \times 30 m2 . The data included in the images were radiance values and were processed by a scaling factor of 40 for the images obtained through the VNIR camera in the range of wavelengths from 400 *–* 1400 nm (bands 1–70), and by a scaling factor of 80 for the images obtained by the SWIR camera in the range of wavelengths from 900 *–* 1700 nm (bands 71–242). There were 44 uncalibrated bands among the 242 bands (USGS, EO1H1410532005260110PU_SGS_01).

In order to reduce the time of computation, algorithms were performed only on a selected region - the region displayed in Figure 1(c), which spanned from the rows 5627 to 5801 of the original image.

Preprocessing

Preprocessing is an essential procedure that should be done in remote sensing applications. It plays an important role, being a stage done prior to any form of data analysis and hence is important in hyperspectral image analysis as well. It essentially prepares and structures the dataset to a form, which could be input directly to the algorithm used, in a much efficient and effective manner. Simply, it converts the dataset to a more qualitative and productive form.

Conversion from radiance to reflectance

Hyperspectral image analysis uses reflectance values since it is the property, which varies with the chemical composition of materials. In addition, reduction in between-scene variability can be achieved through a normalisation for solar irradiance. Thus, spectral radiance values were converted to reflectance values by using the following equation (USGS, EO1H1410532005260110PU_SGS_01). The strength of the conversion from radiance to reflectance was acceptable when considering the mean spectral signatures of the three classes as in Figure $2(a)$ for the spectral bands with high signal to noise ratio (SNR).

Standardisation of the dataset

The image chosen for analysis consists of reflectance values of spectral bands obtained for each pixel. Therefore, it is obvious that the dataset could be affected due to factors such as different lighting conditions, different atmospheric conditions, measurement errors, and noise. Therefore, the spectral data of identical pixels would have the possibility of being different, which would lead to inaccuracies in the analysis. In order to remove or minimise the effect of such factors that are not characteristics of the contents of the pixel, the dataset was standardised by zero meaning and normalising with respect to the standard deviation (Oorloff *et al*., 2017) using equations (2) to (5). The smiling effect was not taken into consideration. Solely addressing the biases with respect to mean and standard deviation gave accurate results. Thus, the influence of the smiling effect could be considered negligible.

Classification algorithm - sub component analysis

The first stage of the algorithm follows a similar and Vithana *et al.* (2019). A straightforward method, signature representing reflectance values corresponding illustrate yet mathematically explicable, where each axis (2018). A straightforward method, which considers the vector representation of spectral were remaining so that a single pixel has a spectral to 198 bands. Thus, a single pixel can be represented characteristics of a pixel, has been used. After removing the 44 uncalibrated bands, 198 properly the characteristics of a pixel, has been used. After removing in a 198-dimensional space, which is impossible to represents a spectral band in reflectance units. the 44 uncalibrated bands, 198 properly calibrated bands approach to what is discussed by Ekanayake *et al.* (2018) which considers the vector representation of spectral

The intention of the initial stage was to classify the classes. Moreover, the algorithm discussed by Ekanayake than one component (mixed pixels) along with their pixels in the selected image region under its underlying *et al.* (2018) identifies the pixels that contain more percentages. Since this algorithm requires normalised data, the standardisation mentioned in the earlier section is essential.

Since a large amount of data introduces redundancy and After applying PCA, each pixel can now complexity to the analysis, principal component analysis in a 20-dimensional space. $$
...(13)

$$
\tau = \max(\gamma) \qquad ...(14)
$$

Where.

- $Y =$ percentage affinity vector
- $\tau =$ maximum affinity percentage of the affinity vector and the other terms are the same as before.

The classification criteria used were,

 \triangleright If 50 %, the considered pixel was classified under the class, which has the maximum affinity.

 \triangleright If 50%, the pixel was labelled as a 'mixed pixel' and the percentage of each end member (soil, vegetation and water) was obtained by the percentage affinity vector.

Figure 2(b) shows the classified image according to the above criteria. It is clearly seen that these results show an accurate correlation with the true colour version of the image depicted in Figure $1(c)$. Using the above criteria, the pure unmixed soil pixels were determined. These pixels were noted in order to perform the next step of the algorithm.

Figure 2: (a) The spectra of the three reference vectors created (b); the classified hyperspectral image under soil (brown), vegetation (green), water bodies (blue) and mixed pixels (yellow)

Identification of probable ilmenite deposits

The coastline along the Northeastern region of Sri Lanka around Pulmudai is rich in mineral sand, especially ilmenite. With the intention of identifying probable ilmenite deposits using hyperspectral images obtained by the Hyperion sensor of the Earth Observing - 1 satellite, an algorithm was developed using correlation coefficient analysis and Fisher's discriminant analysis (FDA). The accuracy of the results was further enhanced by utilising a probability-based approach dependent on the spatial distribution of the ilmenite deposit.

Correlation analysis

According to Premaratne & Rowson (2003), the mineral percentages of the soil in the coast around Pulmudai, which is our target region of analysis is as in Table 2.

Then, a reference signature, which is shown in Figure 3, was constructed to represent the soil, which probably would consist of ilmenite. The construction of the reference spectral signature was done by obtaining the lab spectral signatures of the constituents from USGS spectral library (Kokaly et al., 2017) and by weighing each of the spectra by their respective percentages depicted in Table 2, after normalising to remove any biases in the signatures.

However, the lab spectral data generally has a higher SNR compared to the hyperspectral images obtained by the Hyperion sensor. The SNR of the Hyperion sensor depicted in Figure 3(b) shows that the SNR fluctuates with the wavelength whilst having significantly low SNR values at certain ranges of wavelengths. As the data in the regions of low SNR values would not yield useful information and would distort the results, the data in the regions of SNR values below 50 were removed from both the Hyperion dataset as well as the reference signature created.

Ilmenite has unique spectral characteristics, which is explicitly seen even in compounds consisting of ilmenite. This can be clearly seen when comparing the spectral signatures of various types of minerals available in the USGS spectral library (Kokaly *et al*., 2017). Hence, in the process of obtaining a training set of pixels for ilmenite deposits in the region, first, the pixels containing soil were isolated using the classification algorithm

Finally, each pixel was labelled as ilmenite or nonilmenite based on the spectral similarity measure, *α*. If the spectral similarity between a certain pixel and the mean reference spectral signature of ilmenite class was higher than the spectral similarity between that particular pixel and the mean reference spectral signature of nonilmenite class, then that pixel was classified under 'ilmenite', and *vice versa*.

Probability-based approach

In the Pulmudai region, ilmenite has a larger probability to be found in the coastal area. Statistically, there is a larger probability within 600 m from the coast, and from there onwards, the probability of finding ilmenite and probability function of the probability of the distance against the distance of the distance against the distance of the distance of the distance of the distance falls gradually. Thus, a probability density function was approximated in such a way that the probability of finding α was ma ilmenite was constant until 600m. From there onwards, the probability was approximated to fall exponentially considering the joint measure, β was mapped as shown as shown in Figure 5. The spatial information used to $\frac{F1}{}$ Figure 6(b). As expected, the probability-based approx generate the probability density function can be found in based on the spatial distribution of the ilmenite dep Overstreet (1972).

Table 3: Results of the lab testing on the soil samples collected from the locations near Pulmudai

In this paper, the main focus was to develop a universal algorithm to detect ilmenite mineral based on the unique spectral characteristics of the areas where the particular mineral is located. Based on that, an algorithm was built and the lab testing proves that the locations detected by the novel algorithm actually contained ilmenite.

The classification algorithm used in classifying the pixels containing soil was a combination of PCA and comparison of affinity based on Euclidean distance. The classification process resulted in an image similar to the true RGB image. It could further be concluded that the part of the image of a strip in Northeastern Sri Lanka is mainly covered by soil, followed by foliage. Water bodies are much less in the region of consideration.

In the second part of the algorithm, the soil only pixels were solely taken into consideration. A reference spectral signature for ilmenite deposits was created using lab data and it was compared with the pixel signatures of the image. Using a correlation coefficient analysis, a training set was formed by including the highest correlated and the lowest correlated soil only pixels. Then Fisher's discriminant analysis was performed to further separate the two classes – ilmenite, and non-ilmenite and the classification was done by comparing the spectral similarity of each pixel with the mean spectral signatures of the two classes. In order to further enhance the results, a probability-based approach was utilised. A probability density function was designed to determine the probability of finding ilmenite with the distance measured from the coast. Results were generated taking the probability of finding ilmenite into account as well. Eight locations were chosen from those results and soil samples were collected for lab testing, which ultimately proved that all those eight locations contained ilmenite.

A mineral sands deposit, which is suitable for mineral extraction typically has a heavy mineral grade (HM grade) ranging from 0.5 % to above 20 %. It was observed that all eight locations considered for testing contained ilmenite within that range. Some locations contained very high relative percentages of ilmenite (sample no. 3 *–* 12.27 % and sample no. 4 *–* 10.73 % as seen in Table 3). These amounts are suitable for the extraction of the mineral for commercial use. Thus, this indicates that the algorithm established gives accurate results in finding probable ilmenite deposits, which could be used for commercial purposes.

Prior evidence suggested of an ilmenite deposit in the Pulmudai region of Sri Lanka. Thus, the study was based on that particular region only. In addition, due to the lack of hyperspectral databases, the number of satellite hyperspectral images covering the areas in Sri Lanka are minimal. This prevented us from looking into the adjacent areas for the possibility of the existence of ilmenite.

CONCLUSION

The objective of developing an algorithm to detect ilmenite deposits in Pulmudai region using hyperspectral images is successful. This novel algorithm, which is based on feature reduction and classification methods, signal processing techniques and statistical and mathematical tools, proves to give highly accurate results. Lab testing performed on the collected soil samples further validates the results.
